**Abstract:** The compilation of scientific papers dealing with marine annelids (including Sipuncula) along the coasts of Türkiye (Black Sea, Sea of Marmara, Aegean Sea, and Levantine Sea) together with the new records of polychaete species (21 species) presented in this study resulted in a list of 827 species belonging to 63 families. Polychaeta were represented by 782 species, Sipuncula by 21 species, Oligochaeta by 18 species, Hirudinea by 5 species, and Echiura by 1 species. Syllidae (127 species), Spionidae (57 species), and Serpulidae (56 species) were the most species-rich families and their numbers varied among the seas. Most annelid species were benthic (808 species), 14 species were pelagic, and 5 species (leeches) were parasitic. The Aegean Sea had the highest number of species (634 species), followed by the Levantine Sea (566 species) and the Sea of Marmara (479 species). A total of 72 alien annelid species were reported from the region, with the highest number of alien species (64 species) being found in the Levantine Sea and the lowest number of alien species (3 species) in the Black Sea.

**Key words:** Polychaeta, Sipuncula, Hirudinea, checklist, biodiversity

### 1. Introduction

Marine annelids are highly diverse, inhabiting almost all marine habitats and playing crucial roles in ecosystem functioning. There are nearly 14,000 species worldwide (Appeltans et al., 2012) and 1200 species in the Mediterranean Sea (Coll et al., 2010). However, the diversity of annelids in the world's oceans is currently underestimated, with the true diversity estimated to comprise about 37,000 species, twice as many as currently recognized (Appeltans et al., 2012). Along the coasts of Türkiye, 721 species belonging to 60 families were previously reported, of which 23 species were considered questionable (Çınar et al., 2014a). They are highly diverse and abundant in a variety of benthic habitats and are an important part of the food web. Their stolons or reproductive units move from the benthic to the pelagic realm during the breeding season, transferring benthic energy to the pelagic system through the process of benthic–pelagic coupling (Schroeder and Hermans, 1975; Giangrande et al., 1994).

Annelids, and especially polychaetes, are important biological elements in determining the ecological quality status of water bodies, as their communities vary greatly along pollution gradients and some species (r-strategic, opportunistic) can live in highly organically polluted

waters (Pocklington and Wells, 1992; Dean, 2008; Çınar et al., 2015). Changes in their size, abundance, and biomass in relation to water quality make them good indicators of pollution, and several indices have been developed on this basis (Bellan, 1980; Simboura and Zenetos, 2002; Giangrande et al., 2005). Better understanding and monitoring of biodiversity, together with abiotic elements, is critical in determining ecosystem structures, enabling managers to implement realistic ecosystem-based water management strategies (Arkema et al., 2006; Crowder and Norse, 2008). For this reason, species inventory studies reveal not only the biodiversity of a region but also the structural changes in ecosystems that occur over time due to anthropogenic activities including climate change and the introduction of alien species (Çınar et al., 2021; Bianchi et al., 2022).

In this context, a checklist of pelagic and benthic annelids living along the Turkish coasts was published in 2014 (Çınar et al., 2014a). This checklist summarized the studies carried out in the region up to 2014 and the species records in the four seas (Black Sea, Sea of Marmara, Aegean Sea, and Levantine Sea) surrounding Türkiye. It also included a list of alien species and their regional distribution. A decade has now passed since its publication, during which time several detailed studies have been conducted in the region to shed

\* Correspondence: melih.cinar@ege.edu.tr

further light on our understanding of biodiversity (e.g., Kurt-Şahin et al., 2017a, 2017b; Erdoğan-Dereli and Çınar, 2020a; Çınar et al., 2022).

In the present study, a list of all annelid species reported along the Turkish coasts until May 2024 is given together with species newly reported here, and the presence of some species in the region is discussed.

## 2. Materials and methods

The revised species list was compiled from published papers on the marine annelids reported from the coasts of the four seas surrounding Türkiye. Only reports from the territorial waters of Türkiye were considered, but some reports from areas close to the coasts of Türkiye (e.g., Finike Submarine Mountains) were also included in the list. The marine boundary between the Levantine Sea and Aegean Sea was considered to be a straight line passing between the Dalaman River and Rhodes. Species records from the Çanakkale (Dardanelles) and İstanbul (Bosphorus) Straits were added to the Sea of Marmara, as these straits are strongly influenced by the brackish waters of the Black Sea and have two layered water masses, typical of the Sea of Marmara. As the first records of species up to 2014 were given in the 2014 checklist (Çınar et al., 2014a), in this update, species reports from the seas before 2014 are represented with “+” in the checklist unless a missed reference in the past is specified. The WoRMS database was used for the actual taxonomic categories and species names of annelids.<sup>1</sup>

The first records of species after 2014 were included in the list together with their compiled depth and habitat preferences, based on data obtained both before and after 2014. Species whose presence in the region seems to be questionable were also included and discussed. The list provided here is based on species recorded up to May 2024.

In several projects carried out along the coasts of Türkiye, species new to the marine fauna of Türkiye have been reported, some of which are given here for the first time. Coordinates, depths, and habitat characteristics are given in Table 1 and Figure 1. Soft-bottom samples were taken using a standard Van Veen grab or box corer, and hard-bottom samples were obtained with quadrates of 20 × 20 cm. Samples were sieved in the field using 0.5-mm mesh and fixed in 4% formalin. Materials were then transferred to the laboratory, sorted under a stereomicroscope, and preserved in 70% ethanol.

## 3. Results

### 3.1. New records

Within the framework of several national projects, 21 polychaete species were found to be new to the faunal inventory of Türkiye and added to the list presented here

(indicated with “PS” in the column for each sea). These species belong to the families Ampharetidae (*Amphicteis midas*), Cirratulidae (*Aphelochaeta multibranchis*), Eulepethidae (*Grubeulepis katzmanni*), Fabriciidae (*Novafabricia posidoniae*), Flabelligeridae (*Pherusa mikacea*), Glyceridae (*Glycera oxycephala*), Lumbrineridae (*Lumbrineris luciliae*), Nereididae (*Neanthes rubicunda* and *Nereis lamellosa*), Orbiniidae (*Gesaschroederella laubieri* and *Scoloplos haasi*), Polynoidae (*Malmgrenia andreapoli*), Sabellidae (*Branchiomma boholense* and *Claviramus candelus*), Syllidae (*Opisthodonta serratisetosa*, *Parexogone wolfi*, *Proceraea scapularis*, *Procerastea halleziana*, *Procerastea nematodes*, and *Syllis tyrrhena*), and Terebellidae (*Polycirrus medusa*). In addition, six species were identified as new additions to the Black Sea coast of Türkiye, including *Euchone pseudolimnicola*, *Ampharete acutifrons*, *Levinsenia marmarensis*, *Magelona mirabilis*, *Sphaerosyllis taylori*, and *Spiophanes bombyx*. The highest number of new polychaete species was found from the Aegean Sea coast of Türkiye (36 species), followed by the Sea of Marmara (26 species). Only one species (*Polycirrus medusa*) is reported here for the first time from the Levantine coast of Türkiye.

### 3.2. Species list

Until May 2024, together with the new records presented in this study, a total of 827 annelid species belonging to Sipuncula (21 species), Clitellata (23 species), and Polychaeta (783 species) had been reported from the coasts of Türkiye, of which the Black Sea is represented by 211 species, the Sea of Marmara by 479 species, the Aegean Sea by 634 species, and the Levantine Sea by 566 species (Table 2; Figure 2).

The class Polychaeta ranked first in terms of the number of species (782 species in total) along the coasts of Türkiye, accounting for 96.7% (208 species) and 96% (544 species) of all species in the Black Sea and Levantine Sea, respectively (Figure 2). The order Sipuncula has 21 species in the region, most of which inhabit shallow-water benthic habitats of the Levantine Sea (18 species) and Aegean Sea (17 species). Only one species of this order, *Nephasoma* (*Nephasoma diaphanes diaphanes*), was reported from the Black Sea, near the Bosphorus entrance to the Black Sea. A total of 18 Oligochaeta species were identified in marine and brackish waters (coastal lagoons) of Türkiye, of which 11 species were found in the Aegean Sea. No marine oligochaete species was reported from the Levantine coast of Türkiye. Five leeches (subclass Hirudinea) were found in the region, infecting various bony and cartilaginous fishes, including *Trachinus draco* and *Pteromylaeus bovinus*. The subclass Echiura is represented by only one species, *Bonellia viridis*, which occurs in all seas around Türkiye except the Black Sea.

A total of 57 polychaete families were reported from the coasts of Türkiye. The diversity of the families varied among the seas (Figure 3). The families with the highest numbers of species were Syllidae (127 species), Spionidae (57 species), and Serpulidae (56 species). However, their diversity decreases from south to north. In the Black Sea, Syllidae and Spionidae accounted for almost 30%–36% of the total number of species of these families known from Türkiye. The number of serpulid species increased significantly from north to south, reaching its minimum

(8 species, 14% of all species) in the Black Sea and its maximum (44 species, 79%) in the Levantine Sea. A total of 20 families (e.g., Lumbrineridae, Flabelligeridae) have no species in the Black Sea, 3 families (Eulepethidae, Longosomatidae, and Apistobranchidae) have no species in the Sea of Marmara, 4 families (pelagic families and Nerillidae) have no species in the Aegean Sea, and 4 families (Eulepethidae, Longosomatidae, Apistobranchidae, and Nerillidae) have no species in the Levantine Sea.

**Figure 1.** Map of the stations from which new polychaete records are given. SM: Sea of Marmara.

**Table 2.** Species list of marine annelids from Türkiye and their first reports in each sea. \*: Alien species; BS: Black Sea; SM: Sea of Marmara; AS: Aegean Sea; LS: Levantine Sea; DR: depth range (I: 0–10 m; II: 11–50 m; III: 51–100 m; IV: 101–200 m; V: 201–400 m; VI: 401–600 m; VII: >600 m); H: habitat (Hs: hard substratum, including algae, sponge, mussels, etc.; Ss: soft substratum, including all phanerogams; P: pelagic; Pz: parasite); PS: present study (superscripted number corresponds to station number depicted in Figure 1). ### 3.3. Overview of research on Annelida

Research on Annelida along the coasts of Türkiye started at different times, first in 1948 (Jakubova, 1948; Nikitin, 1948) for the Black Sea, in 1885 (Colombo, 1885) for the Sea of Marmara, in 1865 (Quatrefages, 1865) for the Aegean Sea, and in 1895 (Marenzeller, 1895) for the Levantine Sea.

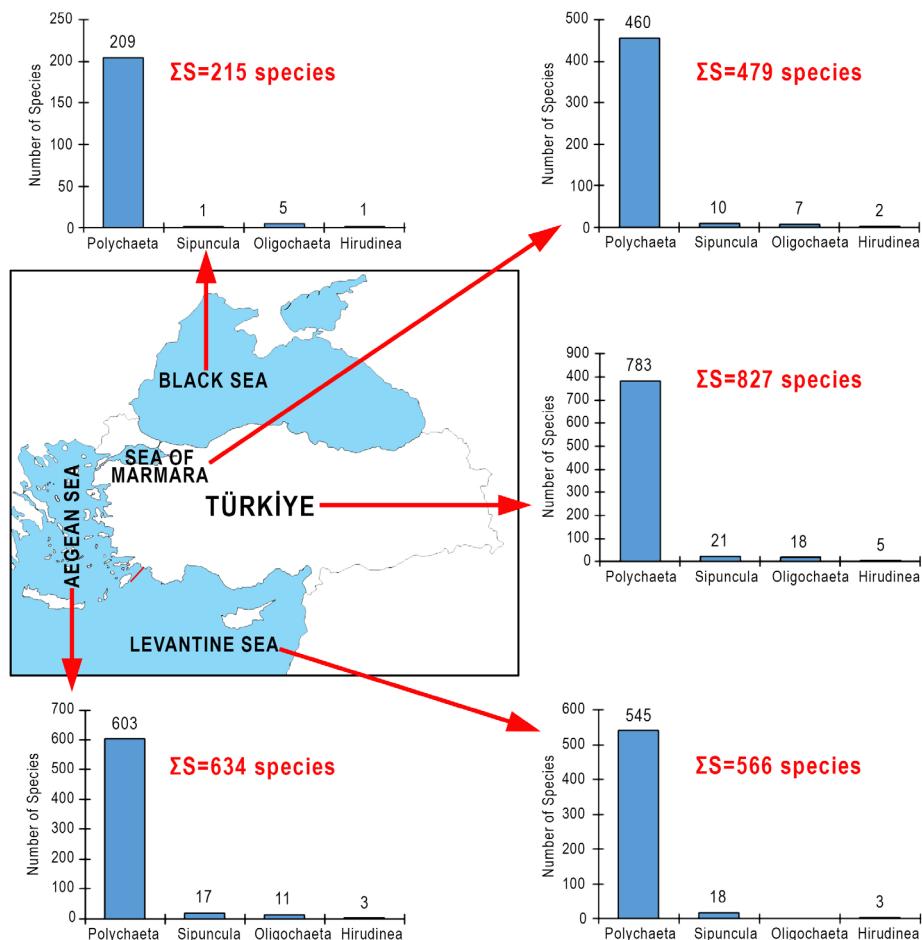

The study of annelids along the Turkish coast of the Black Sea was begun relatively recently compared to other coasts of Türkiye and early studies concentrated mainly on the so-called pre-Bosphorus regions (Jakubova, 1948; Dumitrescu, 1962). Only Nikitin (1948) studied benthic assemblages in the southeastern part of the Black Sea and reported several polychaete species. While only 93 species were known from this sea until 2000, the number of species was reported as 215 in 2024, reflecting the extent of recent scientific efforts on the coast (e.g., Çınar and Gönlügü-Demirci, 2005; Kuş and Kurt-Şahin, 2016; Kurt-Şahin et al., 2017a, 2017b, 2019; Kuş et al., 2021) (Figure 4).

The Sea of Marmara, located between the Black Sea and the Aegean Sea, has received special attention from foreign researchers, with relatively comprehensive studies being carried out in the region before 1900 (Ostroumoff, 1894, 1896). While the diversity of annelids in other seas of Türkiye was seldom documented between 1950 and 1970,

Rullier (1963) and Demir (1952) recorded 112 polychaete species new to the region. After a long period of stagnation (between 1965 and 1995), significant contributions (e.g., Çınar et al., 2011, 2014a; Erdoğan-Dereli and Çınar, 2020a) were made for the elucidation of polychaete diversity in the region and a total of 263 new polychaete species (55% of the total number of species) have been recorded from the area in the last 24 years (Figure 4).

In the Aegean Sea, only 4 species (*Hydroides dianthus*, *Hermodice carunculata*, *Naiades cantrainii*, and *Vanadis formosa*) were reported by Quatrefages (1865), Baird (1870), and Wesenberg-Lund (1939) from the Anatolian coast before the 1940s. Reports of polychaetes increased with the establishment of the Marine Biology Laboratory of Ege University in İzmir Bay in 1965 and received a further boost in the 2000s with the publications by Çınar and Ergen (2002), Ergen et al. (2006), and Çınar et al. (2012). In this paper, 37 new records are being given for the first time for this sea.

The polychaete diversity along the Levantine coast of Türkiye was first intensively studied by Ergen and Çınar (1997), who gave 106 new records for the coast while only 28 species had been known in the region before their study. The first such attempt was made by Marenzeller (1895), who found seven species (*Hyalinoecia tubicola*,

**Figure 2.** Numbers of annelid species along the coasts of Türkiye.

*Euratella salmacidis*, *Apomatus similis*, *Janita fimbriata*, *Metavermilia multicristata*, *Placostegus tridentatus*, and *Salmicina incrustans*) off the Finike (Bunda) Cape and Anamur Cape at depths of 390–943 m. Two recent studies (Çınar et al., 2014a, 2022) significantly increased the number of polychaete species known from this coast.

### 3.4. Depth and habitat distribution

The highest number of annelid species (600 species) was found in the depth interval of 11–50 m, followed by 0–10 m (551 species) (Figure 5). Species diversity decreased with increasing depth and only 12 species were encountered at depths beyond 600 m. In the deep sea (>200 m), only 47 species (5.7% of the total number of species) were found, indicating a low level of scientific effort performed in this environment to date. Eleven species (*Drieschia pelagica*, *Naiades cantrainii*, *Tomopteris vitrina*, *Augeneria profundicola*, *Aricidea mirunekoa*, *Aciculaspio anaximanderi*, *Spiophanes mediterraneus*, *Heterospio mediterranea*, *Fauvelicirratulus dollfusi*, *Apomatus similis*, and *Filogranula gracilis*) inhabited only deep-sea pelagic and

benthic habitats (>200 m). Four species, namely *Nephthys hombergii*, *Prionospio dubia*, *Amphitritides gracilis*, and *Pista cristata*, were widespread and occurred at all depth intervals.

The majority of species (487 species) reported from the coasts of Türkiye were found only in soft substrata, while 98 species were found only in hard substrata, 213 species were found in both hard and soft substrata, and 14 species were found only in pelagic habitats.

### 3.5. Alien species

As of May 2024, a total of 72 alien species had been reported from the coasts of Türkiye, of which only 2 (*Aspidosiphon elegans* and *Nephasoma eremita*) belong to Sipuncula, while the rest (70 species) belong to Polychaeta (Figure 6). The number of alien annelid species varies from sea to sea, reaching a maximum (64 species) in the Levantine Sea and a minimum (3 species) in the Black Sea. The families with higher numbers of alien species are Serpulidae (13 species) and Spionidae (11 species). Alien sipunculan species were found only in the Aegean Sea and Levantine Sea.

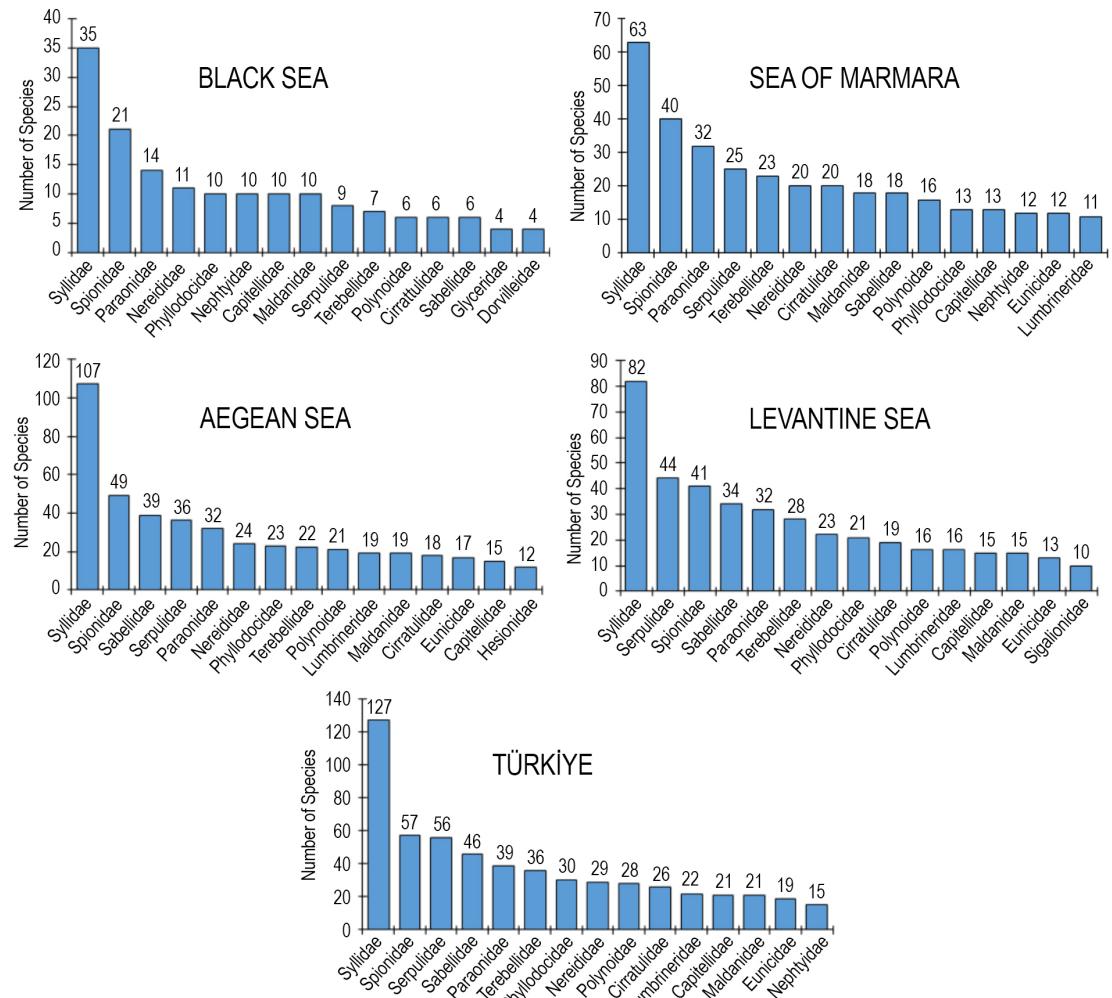

Figure 3. Numbers of species of the top 15 families along the coasts of Türkiye.

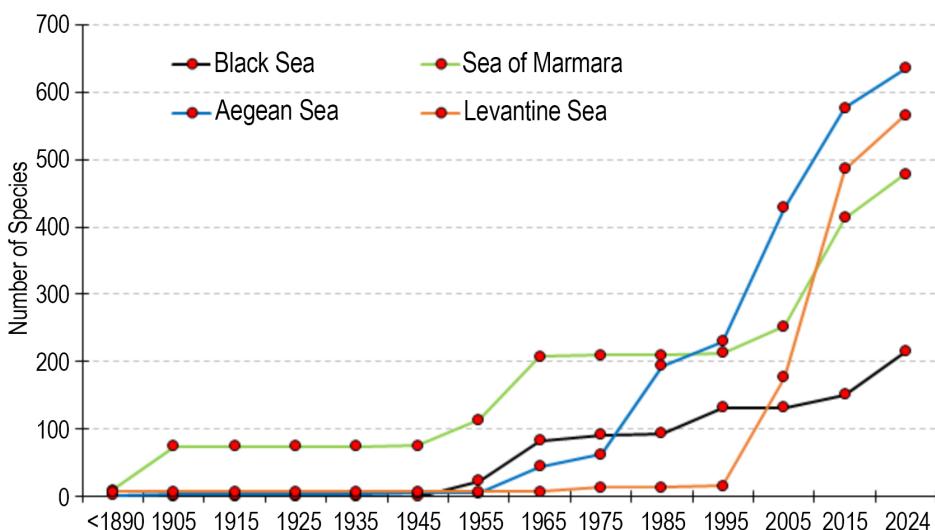

Figure 4. Yearly changes in the numbers of annelid species along the coasts of Türkiye.

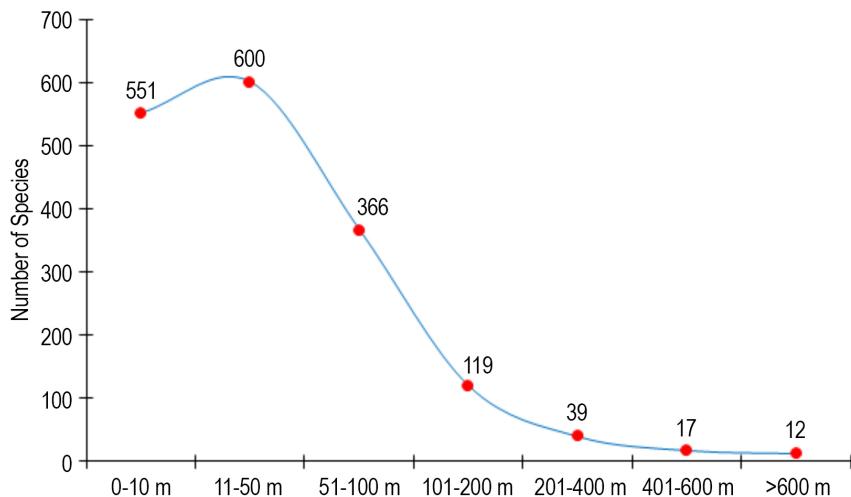

Figure 5. Numbers of annelid species reported at different depth intervals along the coasts of Türkiye.

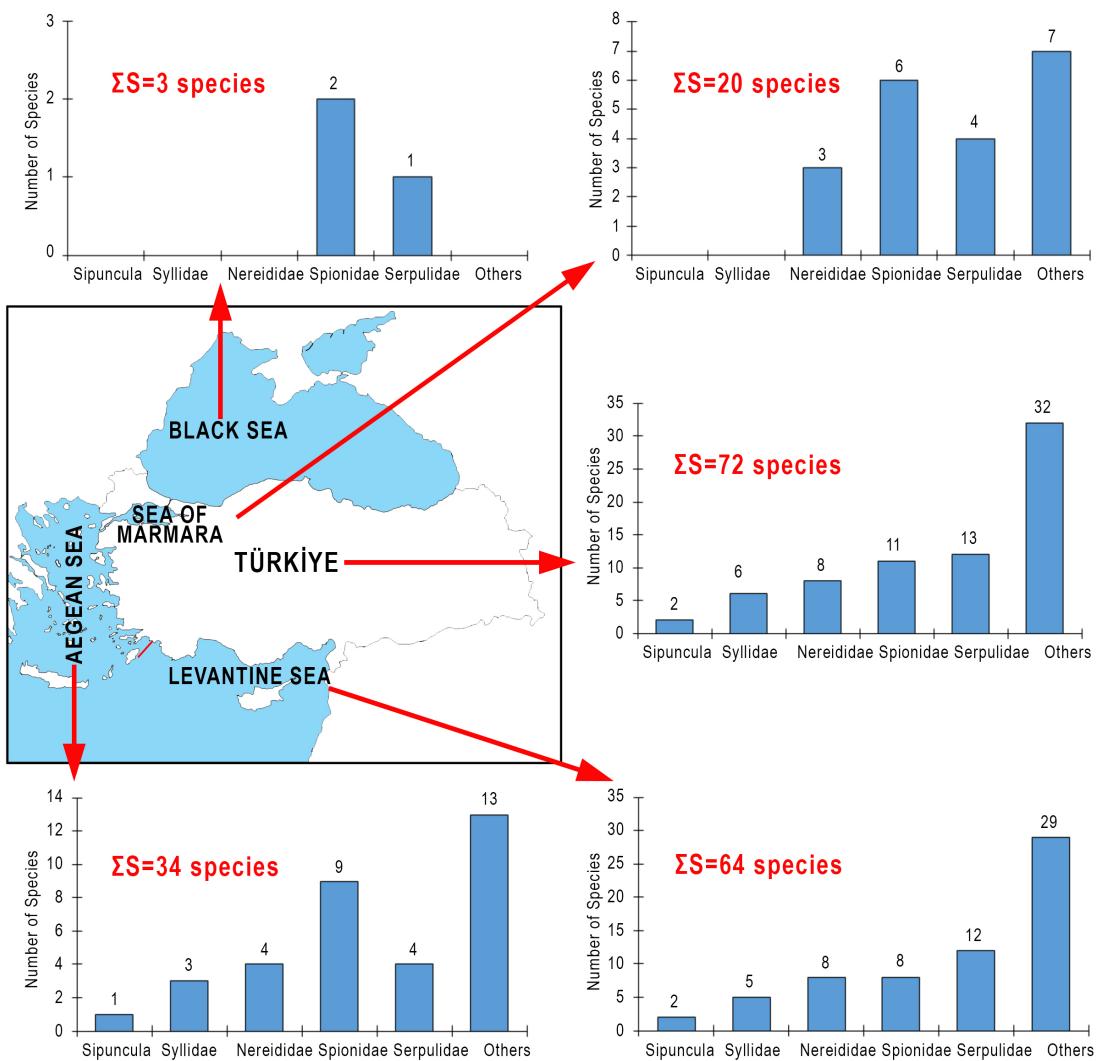

Figure 6. Numbers of alien annelid species along the coasts of Türkiye.

#### 4. Discussion

The number of marine annelid species known from the coasts of Türkiye has increased significantly since the publication of the first checklist in 2014 (Çınar et al., 2014a), from 721 species to 805 species, excluding Sipuncula and Echiura, which were treated as different phyla in 2014. With the new records given in the present study, the number of Polychaeta species increased to 782, representing almost 70% of the Mediterranean polychaete fauna (Coll et al., 2010). In the neighboring Aegean and Ionian seas, Faulwetter et al. (2017) reported a total of 836 polychaete species, of which 610 species were considered as valid records, 84 species were excluded from the list, and 142 species were regarded as questionable. In the Adriatic Sea, the number of polychaete species was reported as 764 (Mikac, 2015), with the richest families being Syllidae (112 species, representing 14.7% of the total polychaete fauna), Serpulidae (50 species, 6.5%), and Sabellidae (46 species, 6%). In Türkiye, the top three families in terms of numbers of species are Syllidae (127 species, accounting for 16.2% of the total polychaete species), Spionidae (57 species, 7.3%), and Serpulidae (56 species, 7.2%). Along the coasts of northern and southern Cyprus, 585 polychaete species are known, with Syllidae (100 species, 17%), Serpulidae (44 species, 7.5%), and Sabellidae (39 species, 6.7%) being the most speciose families (Rousou et al., 2023). With relatively short coastlines, Algeria and Tunisia were reported to have 534 and 390 polychaete species, respectively (Bakalem et al., 2020; Ayari-Kliti et al., 2022). Although not recently revised, the Italian coasts are inhabited by 876 polychaete species (Castelli et al., 2008) and the French Mediterranean coast by 641 species (Dauvin et al., 2006).

The records of several polychaete species (e.g., *Anguillostylis capensis* Day, 1963; *Antinoe epitoca* Monro, 1930; *Euthelepus kinsemboensis* Augener, 1918) given by Mutlu (2020) for the Levantine coast of Türkiye were excluded from the present checklist because their presence in the Mediterranean is highly questionable. They are species mainly known from the South African coast and were presented in Day's monographs (1967), which are inappropriate for species identification in the Mediterranean Sea.

The species given as *Onuphis eremita oculata*, *Streblosoma comatus*, and *Erinaceusyllis belizensis* in the 2014 checklist subsequently proved to be *Onuphis eremita*, *S. pseudocomatus*, and *E. defneae*, respectively (Arias and Paxton, 2014; Lezzi and Giangrande, 2018; Çınar and Erdoğan-Dereli, 2023). The first two species were previously considered as alien species for the Mediterranean (Çınar, 2009) but are now accepted as native species.

The taxonomic statuses of some polychaete species reported from the coasts of Türkiye have not yet been resolved and those species were classified as questionable

in the list presented here. These species were also recognized as questionable in the 2014 checklist (Çınar et al., 2014a). Some species such as *Lepidonotus carinulatus*, *Dasybranchus carneus*, and *Synelmis rigida* were identified by Rullier (1963) in the Sea of Marmara and have not been reported from the region since then. New data are required to clarify their status in the Mediterranean Sea. It would be better to keep them in the list to track reports until concrete evidence on their taxonomic status emerges.

Detailed studies have shown that the records of some "cosmopolitan" species actually belong to several distinct species. For example, *Levinsenia gracilis*, originally described from Denmark, was recorded from different parts of the world's oceans and considered as a cosmopolitan species (Levinsen, 1883; Mesnil and Caullery, 1898; Eliason, 1920; Monroe, 1930). This species was also reported from the coasts of Türkiye (Dumitrescu, 1960, Çınar et al., 1998; Mutlu et al., 2010). However, reexamination of old and new materials from the region revealed that specimens given under the name *L. gracilis* actually belonged to 7 new species: *Levinsenia demiri*, *L. kosswigi*, *L. longobranchiata*, *L. marmarensis*, *L. materi*, *L. tribranchiata*, and *L. vulgaris* (Çınar et al., 2011; Çınar and Dağlı, 2013; Erdoğan-Dereli and Çınar, 2021).

*Paradoneis lyra* is another example of a questionable species. It was originally described from Ireland and has long been considered a cosmopolitan species (Eliason, 1920; Reish, 1968; Imajima, 1973; Laubier and Ramos, 1974; Strelzov, 1979; Aguado and López, 2003). The main characters of the genus are the presence of lyrate chaeta, the number of pairs of gills, and the structure of the notopodial postchaetal lobes. However, it has been shown that the branch thickness of the lyrate chaeta, the ratio of branch lengths to each other, and the shape of the gill pairs and notopodial lobes are also diagnostic characters for species discrimination (Castelli, 1985; Erdoğan-Dereli and Çınar, 2019). The previous records of *P. lyra* from the coasts of Türkiye proved to belong to four different species, namely *P. armata*, *P. ilvana*, *P. longifurcata*, and *P. heterochaeta* (Erdoğan-Dereli and Çınar, 2019).

A study on the family Nephtyidae, based on material collected mainly from the Sea of Marmara and the Black Sea, identified *Inermonephthys turcica* and *Nephthys sinopensis* as species new to science (Kuş et al., 2021), which are morphologically very similar to species previously reported from these areas, namely *I. inermis*, *I. foretmontardoi*, and *N. cirrosa*. However, *N. sinopensis* differs from *N. cirrosa* mainly in the shape of the prostomium (square-shaped) and the ventral cirri on chaetiger 1 (digitiform). *Inermonephthys turcica* differs from the other *Inermonephthys* species reported from the region in having well-developed neuropodial postchaetal lamellae in the anterior and middle regions and barred

chaetae in the preacicula area of the noto- and neuropodia (see Kuş et al., 2021). Therefore, the reports of *I. inermis*, *I. foremontardoii*, and *N. cirrosa* should be reexamined to determine whether these species really exist in the region.

The family Terebellidae is one of the least studied polychaete families in the Mediterranean Sea. Some recent attempts (e.g., Mikac and Hutchings, 2017; Lavesque, et al., 2021) have discovered several new species originally given under the name *Pista cristata*, which is actually a northeastern Atlantic species. The diversity of this family is being studied in Türkiye and two new *Polycirrus* species (*P. karadenizicus* and *P. rhombolabiatus*) (Çınar and Erdoğan-Dereli, 2023) have already been described from material from the Black Sea. In the present study, *Polycirrus medusa* was reported for the first time from the Sea of Marmara, the Aegean Sea, and the Levantine Sea, indicating its widespread distribution in the area, and it could have previously been confused with closely related species.

Three species, namely *Salvatoria dolichopoda*, *Glycera rouxii*, and *Lysidice margaritacea*, which were previously synonymized with *S. clavata*, *G. unicornis*, and *L. ninetta*, respectively (Fauvel, 1923; Böggemann, 2002), were considered valid in this study, as they show distinctive morphological features when compared to closely related species. *Salvatoria dolichopoda* has a distinctive color pattern on the dorsum that is absent in *S. clavata* (Kurt-Şahin et al., 2019). *Glycera rouxii* differs from *G. unicornis* in the shape of the pre- and postchaetal lobes on the parapodia, the shape of the proboscis papillae, and the shape of the branchiae (Parapar et al., 2015). *Lysidice margaritacea* has maxillary III with 2 large accessory teeth and 1 small accessory tooth (4 teeth in *L. ninetta* and *L. collaris*) (Kurt-Şahin and Çınar, 2009).

The alien species inhabiting the coasts of Türkiye were recently revised and 2 sipunculan and 65 polychaete species were listed (Çınar et al., 2021b). In this paper, the number of polychaete species increased to 70, while the number of sipunculan species remained the same. *Leonnates aylaoberi*, *Glycera cinnamomea*, *Barantolla cryptogenica*, and *Branchiomma boholense* are presented here as new additions to the marine alien species of Türkiye, while *Hydroides dianthus* was previously included in the list (Çınar et al., 2011) and later excluded from the list after molecular analysis of the species showed its native status in the Mediterranean Sea (Sun et al., 2017). However, more recent studies have supported its nonnative status in the region (Grosse et al., 2021; Langeneck et al., 2024); thus, it has been reincluded in the list. *Leonnates aylaoberi* was originally described from the coasts of Türkiye (Çınar and Dağlı, 2013) and considered a native species, although the genus showed Indo-Pacific affinity and other species of the genus in the Mediterranean are known to be alien. In this context, Rousou et al. (2023) considered

it an alien species (cryptogenic) for the Mediterranean, although its distribution outside the Mediterranean is currently unknown. There is always the possibility that a species first described from the region may turn out to be an alien species, and there are examples of such cases in the Mediterranean. For instance, *Syllis ergeni* was first described in the polluted inner part of İzmir Bay (Aegean Sea) and found to occur densely on the southern coast of Türkiye, located close to the Suez Canal. It was later found to occur in the Red Sea and Australia and the status of the species was changed from native to alien (Çınar et al., 2017; San Martín et al., 2024).

A similar situation can be seen for the capitellid *Barantolla cryptogenica*, which was first described from the southern coast of Türkiye by Çınar et al. (2022). In a long-term monitoring study, this species was absent from monitoring stations before 2015 and was detected for the first time in 2015 with one or two individuals. Later, it dominated the stations in 2018 and 2019, with a maximum density of 460 ind. m<sup>-2</sup> (Çınar et al., 2022). This species was found to be exceptionally abundant in samples collected off Yumurtalık (İskenderun Bay) in July 2023, reaching a population density of 2210 ind. m<sup>-2</sup> at one station (25 m depth), where 53% of the total number of individuals belonged to this species (unpublished data). This species could have been introduced to the region from an unknown region possibly via the ballast water of ships, as the Yumurtalık region has a large oil terminal frequented by ships arriving from different parts of the world.

*Branchiomma boholense* was previously confused with *B. bairdi*, both of which are alien species for the Mediterranean and have macrostyloides on the radioles, unlike other Mediterranean *Branchiomma* species. The differentiation of these species was based on the size of the worms (larger in *B. boholense*) and the eyes (larger in *B. bairdi*), as well as the shape of the radioles (Del Pasqua et al., 2018). *Glycera cinnamomea* was classified as a casual alien species because only one specimen was found on a sandy muddy bottom at a depth of 9 m in Mersin Bay, near Taşucu (Dağlı and Çınar, 2022). This species has a specific character (nonretractable branchiae with a maximum of five rami) and has previously been reported from the Indo-Pacific and the Red Sea (Suez Bay), suggesting a possible route of introduction. No other records of this species have been reported to date; thus, it remains a casual species.

Based on DNA analysis, Simon et al. (2019) postulated that *Spirobranchus kraussi* is a complex species and its actual distribution is restricted to the coasts of South Africa. The taxonomic entity of the invasive alien species identified as *S. kraussi* in the eastern Mediterranean (Çınar, 2006) is unknown at this time and it is therefore given with "cf." in the revised checklist.

The number of annelid species reported from the coasts of Türkiye increased sharply after 1995, demonstrating the correlation between the level of scientific effort and the level of accurate representation of biodiversity. The monitoring studies organized by governmental ministries, especially the Ministry of Environment, Urbanization, and Climate Change, and municipalities have played a pivotal role in adequately assessing coastal biodiversity and its changes over the years and in discovering new species and records. Scientific projects conducted by TÜBİTAK and universities have also contributed to an improved understanding of the true biodiversity of habitats and regions. Such initiatives, together with new training

programs for young scientists, are needed for the future assessment of biodiversity as anthropogenic impacts and climate change continue with an increasing trend.

### Acknowledgments

New data in this study were obtained from TÜBİTAK projects (104Y065 and 111Y268) and from the monitoring project DEN-İZ (Integrated Marine Pollution Monitoring Programme) carried out by the Ministry of Environment, Urbanization, and Climate Change/General Directorate of Environmental Impact Assessment and coordinated by the TÜBİTAK Marmara Research Center. We would like to thank our colleagues for obtaining and sorting materials.
